With 780-nm, 250-fs laser pulses, ultrafast optical nonlinearity has been observed in a series of thin films containing poly(methyl methacrylate) (PMMA)-TiO2 nanocomposites, which are synthesized by a simple technique of in-situ sol-gel/polymerization. The best figures of merit are found in one of the films prepared with a 60 wt % of titanium isopropoxide. Transmission electron microscopy shows the presence of 5-nm-diameter particles in the film. The observed optical nonlinearity has a recovery time of ~1.5 ps. These findings suggest the strong potential of PMMA-TiO2 nanocomposites for all-optical switching. © 2003 American Institute of Physics. [DOI: 10.1063/1.1568544]

Nanoscale composite materials containing titanium oxides are interesting because of their potential applications in optoelectronic devices.1,2 A great deal of research effort has been focused on both synthesis of high-quality, transparent films consisting of polymer-TiO2 hybrid nanocomposites, and on their linear optical properties.3–7 Recently, the nonlinear optical properties of such materials have also received attention. The third-order optical nonlinearity (χ(3)=4.1 ×10−11 esu) in TiO2 nanocrystalline particles dispersed in SiO2 was measured at 1.06 μm with nanosecond laser pulses.8 A large, reverse-saturable type of nonlinear absorption was also observed in poly(styrene maleic anhydride)/TiO2 nanocomposites with a continuous-wave He-Ne laser beam.9 Here, we report our investigation into ultrafast optical nonlinearity in a series of thin films of poly(methyl methacrylate) (PMMA)-TiO2 nanocomposites. Our results show that such nanocomposites possess very large and ultrafast optical nonlinearity, and have a great potential for optical switching and optical communications.

The thin films of PMMA-TiO2 nanocomposites were prepared based on a modification of a reported method.7 Monomers, methyl methacrylate (MMA) and 3-(trimethoxysilyl) propyl methacrylate (MSMA), and an initiator benzoyl peroxide (BPO) in tetrahydrofuran were added into a reaction flask and polymerized at 60 °C for 1 h. The molar ratio of MSMA to MMA+ MSMA was 0.25, and the amount of BPO that was added to this mixture was fixed at 3.75 mol %. On the other hand, a TiO2-based solution was prepared using titanium isopropoxide (Ti-iP), deionized water, ethyl alcohol, and hydrochloric acid, according to the method described elsewhere.10 Ti-iP was first mixed with ethanol in a container and stirred for 30 min. A mixture of deionized water and HCl was poured under stirring into the transparent solution to promote hydrolysis. The Ti-iP concentration in the solution was fixed at 0.4 M with an understoichiometric ratio of water to Ti-iP (rw) of 0.82. A pH value of 1.3 was used to obtain a stable solution (i.e., with longest gelation time). Furthermore, this homogeneous mixture was added dropwise over 30 min into the polymerized monomers with rigorous stirring to avoid local inhomogeneities. The reaction was allowed to proceed at 60 °C for another 2 h. Finally, five films according to the Ti-iP weight percentage in the preparation (i.e., 20, 40, 60, 80, and 100 wt %, labeled as T20, T40, T60, T80, and T100, respectively,) were prepared by the following procedure. Each solution was spin-coated on quartz substrates at 3000 rpm for 20 s. Prior to the spin coating, the substrates were carefully cleaned, first in a diluted HNO3 solution in an ultrasound bath. After a thorough rinsing in running water, the ultrasound bath treatment was repeated with distilled water, acetone, and ethanol. The substrates were then dried and stored in the drying oven at 40 °C. The coated films were then baked in two stages of curing temperatures to finish the polymerization: at 60 °C for 30 min and 150 °C for 3 h. The thickness of the films was measured to vary from 250 to 350 nm by a surface profiler (Alpha-Step 500).

All the films are transparent to the human eye and their linear transmittance is 80%–90% at 780 nm. Figure 1(a) displays their (αhν)1/2 spectra, where α is the linear absorption coefficient and hν is the photon energy. The absorption onsets change unmonotonically as the titanium content increases. As the weight percentage of Ti-iP increases from 20% to 60%, there is a red shift in the absorption, consistent with published reports.4,5,7,8 The maximum redshift is found in the T60 film, which also has an absorption tail spanning the entire visible spectrum due to the formation of nanoparticles. In Fig. 1(b), the high-resolution transmission electron microscopy (TEM) clearly shows the presence of the nanoparticles, and Fig. 1(c) shows their size distribution, with an average diameter of 5 nm. These particles give rise to loss through Rayleigh scattering, which is commonly associated with guest–host structures with different refractive indices for guest and host materials.2 In addition, weak confinement may also contribute to the absorption below the band-gap...
energy. The exciton Bohr radius $a_B$ in bulk TiO$_2$ solid is 0.8 nm if the effective masses ($m_e = 10 m_0$ and $m_h = 0.8 m_0$) are used. In the nanoparticles, the exciton energy can be estimated by using the Brus formula: $E_{\text{exc}} = E_g + R_y \left( \frac{\pi^2 a_B^2}{R^2} - 3.6 \frac{a_B}{R} \right)$, where $R_y$ is the Rydberg energy unit, $E_g (= 3.2 \text{ eV})$ is the band-gap energy of anatase TiO$_2$ solid, and $R$ is the particle radius. Two terms in the parentheses represent kinetic energy and Coulomb interaction.

With $R = \approx 2.5 \text{ nm}$, we find there is a redshift for the exciton energy, located $\approx 3.16 \text{ eV}$. Note that our TEM evidence confirms much less or no formation of nanoparticles in the T80 and T100 films, which explains a reverse (blue) shift in the absorption as the titanium contents increase further. For the T100 film, the measured energy gap of 3.2 eV implies that the titanium oxides should be TiO$_2$ in the anatase crystalline phase.

The nonlinear optical properties of the PMMA-TiO$_2$ films were measured by Z-scan technique with 250-fs laser pulses at 780 nm. Figure 2(a) shows an example of open-aperture and closed-aperture Z-scans performed in two different repetition rates of 0.4 kHz and 4 MHz, respectively, on the T60 film. The results show no significant difference between these Z-scans, indicating that laser-induced thermal lensing effects are negligible. The intensity independence of the Z-scans in Fig. 2(b) shows pure third-order nonlinear processes for the observed nonlinearities. Therefore, the nonlinear absorption and refraction can be described by $\Delta \alpha = \beta I$ and $\Delta n = n_2 I$, where $\beta$ and $n_2$ are the nonlinear absorption coefficient and nonlinear refractive index, respectively, and $I$ is the light intensity. Both $\beta$ and $n_2$ values can be extracted from the best fitting between the Z-scan theory and the data.

Figure 2(c) displays both $\beta$ and $n_2$ values of the five films plotted as a function of the weight percentage of Ti-iP in PMMA.
linear absorption, with $\beta = 1.4 \times 10^{3}$ cm/GW, or Im($\chi^{(3)}$) = $0.89 \times 10^{-9}$ esu, which is about 100 times larger than that for a rutile crystal of TiO$_2$, measured at 532 nm. We attribute this enhancement to the resonance with the exciton transition at $\sim 3.16$ eV since the two-photon energy of the laser pulses is 3.18 eV. Unfortunately, theoretical values of the two-photon absorption for TiO$_2$ nanoparticles are unavailable from literature. However, the two-photon absorption cross sections of $\sim 10^{-46}$ cm$^3$ s$^{-1}$ have been calculated for two-photon-allowed transitions in CdSe nanocrystals 2.9 nm in diameter. For comparison, our data show that the two-photon absorption cross sections are in the range from $10^{-46}$ to $10^{-45}$ cm$^3$ s$^{-1}$ for the PMMA-TiO$_2$ nanocomposites.

Similarly, the highest $n_2$ [eq (1)] is also found in the T60 film, about two orders of magnitude higher than that measured by Zhou et al. on TiO$_2$/SiO$_2$ nanocomposites at 1.06 µm.$^2$ Such a large difference is anticipated for the following reasons: (1) the dispersion of the nonlinear refraction, and in particular, our measured value, is enhanced by the two-photon resonance; (2) different size and volume fraction, and in particular, Zhou’s result, was obtained from TiO$_2$/SiO$_2$ nanocomposites of larger sizes (20–50 nm), in which $\chi^{(3)}$ should be expected to approach the bulk value; and (3) different host materials. The positive sign of the measured $n_2$ is in agreement with theories for a photon energy that is nearly half of the transition energy.$^6$

The optical nonlinearities in the T100 film are too small to be detected accurately. We employ the two-band theory$^6$ to estimate $\beta$ and $n_2$, because this film is a layer of anatase TiO$_2$, as indicated by both TEM and absorption spectrum studies. The estimated values are at least two orders of the magnitude smaller than those found in the T60 film, which are very close to or below the sensitivity of our detection system. To evaluate the material requirements for all-optical switching devices, we calculate the following figures of merit for each thin film, $W=n_2I/\alpha_0\lambda$, and $T=\beta^2/n_2$. For $\lambda = 780$ nm and $I=5.9$ GW/cm$^2$, the best figures of merit have been obtained from the T60 film, in which $W=1.2$ and $T=4.3$, close to the target values of $W>1$ and $T<1$.

To assess the response time of the observed nonlinearity in the PMMA-TiO$_2$ thin films, we performed a degenerate femtosecond time-resolved pump-probe technique. Figure 3 displays transient nonlinear absorption signals of the films. Except for the T100 film, the temporal profile of each signal consists of two components, shown by the fits using two exponentially decay terms. The first is an instantaneous component, which is determined by the laser pulse duration (250 fs). Another one is a slowly decaying component with a characteristic time about 1.5 ps, with the accurate times depending on the weight percentage of Ti-iP. This slow decay is due to the relaxation of excitons excited by the two-photon absorption. The largest nonlinear absorption signal, $\Delta T/T^1$, found in the T60 film is consistent with its highest nonlinear absorption measured previously using the Z-scan method. The picosecond recovery time at room temperature suggests great potential applications of this material in optical switching devices.

In conclusion, large optical nonlinearities in the PMMA-TiO$_2$ nanocomposites have been observed using 780-nm, 250-fs laser pulses, and the nonlinear response time has been found to be about 1.5 ps. The best figures of merit have been found in the film using 60 wt% of Ti-iP in preparation. The large optical nonlinearities are believed to be caused by two-photon-resonant exciton in the nanosized particles containing TiO$_2$. Finally it should be pointed out that these films of the nanocomposites are fabricated with a simple sol-gel/polymerization method.
